ABSTRACT

The aim of this work is to verify the role played in chromatographic technique by innovative monoliths in mRNA vaccine production: material used, technology, and products for large-scale production. The fact that a great producer uses carbon composite in monoliths is of great interest: carbon fiber reinforcement embedded into epoxy thermoset resin. It also verified the role played by silica products for chromatographic use and their origin (synthetic or natural products like Rice). Related to the product from Rice it is used as a pharmaceutical excipient. Also, in this case, other great chemicals producers on its website for silica gel for chromatography report a reference related to the production of silica from Rice. (not only synthetic so) of interest is the profile of impurity of this product if used in the resin column for purification biopharmaceutical and in particular the carbon content.

Keywords: Biopharmaceuticals, Purification, Chromatography, Resin Column, Monoliths, Silica gel, Carbon content, Graphene, Impurity, Toxicological and Regulatory aspects

INTRODUCTION

In the production of biopharmaceuticals, the purification process is one of the main phases. For example, the production of the innovative mRNA vaccine for covid-19 has used a sequence of chemical-physical processes like Tangential Flow Filtration (TFF), followed by a chromatographic separation (affinity or ion exchange) and then treated with an ultrafiltration/diafiltration process. The various methods of separation were used in the past membrane, or more recently magnetic beads separation, and today used monoliths of composite materials. If the TFF filter is made of plastic materials the chromatographic resin, see uses silica gel or other polymers. In the research field, diagnostics field, and on a small laboratory scale also used graphene carbon coated (resin and magnetic beads). The silica productive process sees a synthetic process or purification – extraction from various natural products like rice husk or diatomea shell. Various literature reports the production of silica from rice also of high quality and purity and some producer sell this product as pharma excipients. But this natural product due to its production process that implies high-temperature treatment show various level of impurity for example related carbon products (99% silica, 1% graphitic). So two interesting questions can be:

1. Silica for rice, due to its lower cost versus synthetic one, is used in resin for large-scale biopharmaceutical production.
2. If used these carbon particles of the rice silica can be found in the impurity of the final product after the purification process?

Stationary phases for adsorption

A packed bed is a column filled with adsorption material (Figure 1). It is the most common and simple stationary phase for adsorption. However, it has some downsides. It shows high-pressure drops and the mass transfer of solutes to and from the adsorption sites is largely dependent on the slow intra-particle diffusion. Packed beds are also susceptible to channeling which is caused to the incomplete use of the column capacity. Recently the stationary phases for bio separations have been improved by using new hybrid adsorption phases such as monoliths, membrane absorbers, or particle-loaded mixed matrix membranes. These stationary phases consist of a very porous structure with interconnected pores such as those found in porous membranes, that allow for uninterrupted bulk flow. The adsorption phase is coated on the porous structure or dispersed as particles in the porous structure. The high porosity and short diffusion paths make very high flow rates possible.

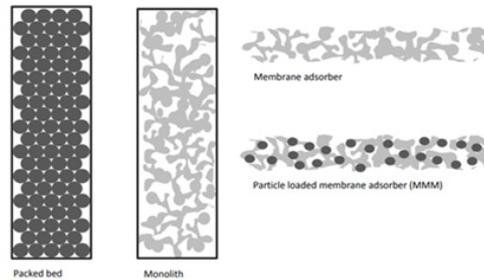

Figure 1. Different stationary phases

Silica gel has a strong physical strength and is the most widely used as a column packing agent for analysis and purification in chromatographies such as HPLC, medium and low-pressure chromatography, and open column chromatography (Figure 2).

Chemical Modification

Chemical modification is to bind various functional groups to silanol groups on the surface of silica gel to change silica gel functions. C₁₈ modified silica gel (ODS) is an octadecyl group-bound silica gel and is suitable for reverse-phase chromatography. NH₂-modified silica gel is an aminopropyl group-bound silica gel and is suitable for normal-phase, hydrophilic interaction, and ion exchange IE chromatography. Unmodified silica gel is mainly used for normal-phase chromatography (Figure 3,4).

Stationary Phase

Monoliths allow a high degree of freedom for the operator since they can be manufactured from various kinds of raw materials (like as polymethacrylate, polyacrylamide, polystyrene, silica, and cryogels) with different morphologies and channel diameters. In general, monolithic media can be classified into 2 categories, namely organic, polymer-based and inorganic, silica-based media. The main advantages of organic, polymer-based media are pH stability and customizability, but the columns are mechanically not very stable, which shortens the column lifetime. Inorganic, silica-based monoliths show excellent stability and separation efficiency. Manufacturing is sophisticated and also time-consuming. Recently in the last years, also organic-inorganic hybrid monoliths have been prepared to combine the advantages of both [1].

Commercially Available Monoliths

Monoliths are a great powerful alternative to particle-based resins for the purification of biomolecules, and the first industrial processes employing monoliths have been launched. Several providers offer monoliths of different chemistries, shapes, and sizes. Polymethacrylate-based monolithic columns are currently produced/distributed by BIA separations (Ljubljana, Slovenia) under the trade name CIM® (Convective Interaction Media), CIMac® (CIM analytical columns) and CIMmultus®. They offer custom-made columns with different column chemistry to suit the needs of the end user. Dionex (CA, USA) also produces polymethacrylate monolithic columns under the trade name ProSwift®. Phenomenex (USA) markets silica-based monolithic columns under the trade name Onyx®. Agilent Technologies (USA) markets poly-(glycidyl methacrylate-co ethylene dimethacrylate) monoliths, made by BIA separations, under the trade name Bio-monolith®. Merck Millipore (USA) has the trade name Chromolith® for marketing their silica-based monolithic columns. Bio-Rad (CA, USA) produces polymer-based monolithic columns under the trade name Uno®.

From ONYX Especially for The Bio Industry the Onyx Monolithic C₁₈ in the 150 mm x 0.1 mm dimension combines high efficiency, peak capacity, and load ability all in a format for nano-LC proteomics applications Carbon Content: 18%. CIMmultus™ from BIA Separations (1mL –8L). Multiuse Disposable Units - “Plug and Play”

“Carbon fiber reinforcement embedded into epoxy thermoset resin (carbon fiber composite); tough, light material; 5-times lower density than stainless steel; operate at 20 bar (291 psi).”

Reverse phase chromatography

RPC is generally best suited for polishing because the extreme hydrophobicity of the solid phase makes it vulnerable to fouling by proteins and aggregates in crude feed streams. Unlike silica-based RPC media, SDVB can be cleaned with 1M NaOH including for periods of a full day or more if necessary (Figure 5).

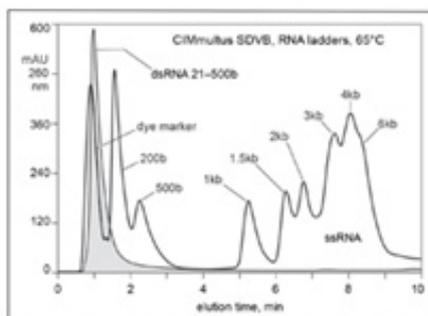

Figure 5. Fractionation of ssRNA and dsRNA ladders on CIMmultus SDVB at 65°C

For chromatographic resins, Nuvia prime 4a and SiliaSphere C₁₈ were chosen. The resins were chosen based on their separation mechanism, which is hydrophobic anion exchange for a prime 4a and C₁₈ Reversed-Phase (RP) for SiliaSphere. Both resins also have large pores of around 1000 Å, allowing pore diffusion to take place. As monoliths, BIA CIMmultus™ PrimaS and Oligo dT18 were modeled [2].

D.N.A. extraction was carried out on silica-based monoliths within a microfluidic device. Solid-phase D.N.A. extraction methodology was applied in which the D.N.A. binds to silica in the presence of a chaotropic salt, such as guanidine hydrochloride, and is eluted in a low ionic strength solution, such as water. The addition of poly-A carrier RNA to the chaotropic salt solution resulted in a marked increase in the effective amount of D.N.A. that could be recovered (25 ng) compared to the absence of RNA (5 ng) using the silica-based monolith. These research findings confirm that techniques utilizing nucleic acid carrier molecules can enhance D.N.A. extraction methodologies in microfluidic applications. Large-scale manufacturing of gene vectors such as plasmid D.N.A. is an important issue in gene therapy. Anion-exchange chromatography AEC is fundamental in the downstream processing of plasmids both as a process and analytical technique [3].

We demonstrate the use of strong anion-exchange AE Fast-Performance Liquid Chromatography (FPLC) as a simple, fast, and robust method for RNA production by the *in vitro* transcription. With this technique, we have purified different transcription templates from unreacted reagents in large quantities. The same buffer system could be used to readily remove nuclease contamination from the over-expressed pyrophosphatase, the important reagent for *in vitro* transcription. The method can be used to monitor *in vitro* transcription reactions to enable facile optimization of reaction conditions, and we have compared the separation performance between strong and weak anion-exchange FPLC for various transcribed RNA.s, including the Diels-Alder ribozyme, the hammerhead ribozyme tRNA., and 4.5S RNA. The functionality of the purified tRNA(Cys) has been confirmed by the aminoacylation assay. Only the purification by strong anion-exchange FPLC has led to the enrichment of the functional tRNA. from run-off transcripts as revealed by both enzymatic and electrophoretic analysis.

The current landscape for the preparative chromatographic RNA purification uses reversed-phase HPLC, but this technique presents many issues with process scale-up and ion exchange for preparative purification has only been used for short RNAs. The invention provides preparative purification of RNA (mRNA) using ion (anion) exchange chromatography AEC that allows for the separation of longer RNAs up to 10,000 nucleotides in length via a scalable method. This method avoids problems with current techniques by using low-pressure chromatography that is agreeable with existing equipment in cGMP commercial facilities, that uses aqueous-bases solutions as the mobile phase (rather than flammable organic solvents), that uses sorbents displaying binding capacities of greater than 10 mg RNA./mL resin (e.g., using larger pore sorbents, >500 Å, that display greater m RNA binding capacities), and that yields desired RNA salt forms for downstream formulation with no additional manipulation necessary (unlike the ion pair reverse phase techniques). The ion exchange IE sorbent can comprise a positively-charged functional group linked to solid phase media. The ion exchange sorbent used can have a binding capacity of greater than 10 mg RNA transcript/mL sorbent, or greater than 12 mg, 15 mg, 20 mg, 25 mg, 30 mg, 35 mg, 40 mg, 45 mg, 50 mg, 55 mg, 60 mg, 100 mg RNA. /mL sorbent or higher, or any value or fractional value in between, or any range including or within these numbers [4].

The sorbent can also have smaller binding capacities of 1 mg to 10 mg RNA transcript/mL sorbent. In some embodiments, the ion exchange sorbent is a porous media. A variety of different particle and pore sizes can be used. Particle sizes can include the standard sizes used in chromatography methods, including sizes in the range of fewer than 1 µm or 1 to 500 µm (e.g., 5 µm, 10 µm, 20 µm, 50 µm, 75 µm, 100 µm, 150. µm), or any number or fractional number in between, or any range including or within these numbers. Larger or smaller sizes can also be used. Particles can include small silica beads or other kinds of particles. Pore sizes can include sizes that are greater than 500 Å, or greater than or equal to 600 Å, 700 Å, 800 Å, 900 Å, 1000 Å, 2000 Å, 4000 Å, or 8000 Å, or any number or fractional number in between, or any range including or within these numbers. Smaller pore sizes can also be used, like 1 Å to 500 Å.

The ion exchange IE sorbent can be poly styrene-divinylbenzene, polymethacrylate, crosslinked agarose, silica, or allyl dextran with N-N-bis acrylamide, among a variety of other sorbents. The ion exchange sorbent can also be a non-porous media, such as a monolithic column. In some embodiments, membrane-based ion exchangers are used, such as MILLIPORE CHROMASORB™ or SARTORIUS SARTOBIND®. In some kind of embodiments, a mixed mode or combination of ion exchangers can be used. As explained above, the ion exchange sorbent or resin can be strong or weak. The term weak resins include resins that have a low affinity for polypeptides and a high affinity for polynucleotides, RNA transcripts. The term weak resins also include resins that have a low affinity for polypeptides and a low affinity for polynucleotides, RNA transcripts.

Described herein are methods of purifying polynucleotides, in RNA and oligonucleotides, probes, primers, and siRNA, using monolithic columns with immobilized ligands coupled to the monolithic column. Also described are the monolithic columns for purifying polynucleotides from a sample; and the methods of preparing such columns. The monolithic matrix may be derived from a variety of materials, such as but not limited to, polymethacrylate, polyacrylamide, polystyrene, silica, and cryogels [5].

Monoliths are considered the fourth generation of chromatographic stationary phases. They are also called continuous beds, consisting of a single piece of highly porous organic or inorganic solid material in a column in form of disk, rods or tubes. The structure of the monoliths avoids the generation of shear forces, thereby contributing to high functional recoveries, even for labile biomolecules such as live virus vaccines, DNA. plasmids, and large proteins. This structural feature eliminates some problems related to the scale-up and scale-down variations of conventional matrices, the packing quality, and the need to repack a column due to the inadvertent introduction of air bubbles. Monoliths also differ from conventional supports in their hydrodynamic properties. "Due to its ultra-high surface area and ability to be functionalized, graphene is suitable for use in many biomedical applications, including gene and drug delivery."

RESEARCH METHODOLOGY

Related to the topics of this work various relevant literature, patents, and another reference from producers are reported and analyzed. All literature comes from a scientific biomedical database. After this review part, an Experimental project hypothesis is submitted to the researcher to produce a global conclusion.

Liquid Chromatography (LC) is used for separating materials in biopharmaceutical production, primarily for purifying proteins by separating products and impurities. The stationary phase SP in liquid chromatography uses fine, solid beads referred to as resins that are packed and held in a column by meshes. These particles can be physically or chemically modified to provide specificity to grab or repel molecules within mixtures (Figure 6).

The chemical compatibility allows resins to be stored in caustic solutions, which can be beneficial due to their antimicrobial properties. Lastly, carbon content is variable (but mostly negligible) from resin to resin compared to proteins.

EKASIL Rice Husk Silica

1. Basic Specifications
2. Advanced Specifications

EKASIL advanced specifications are silica products from rice husk that are developed from the basic specifications based on customers' requirements of physicochemical properties. The specifications are various and applicable to a wide range of user industries. EKASIL 200 PHARMA is high-purity silicon dioxide from rice husk for pharmaceutical uses. High-purity amorphous silica for pharmaceutical uses in all types of dosage forms. Free flow and anti-caking agent to improve powder properties Improving tablets properties such as hardness and friability Used as viscosity increasing agent to thicken and thixotropic liquids used as anti-setting, thickening and anti-sagging agent High purity, low humidity. No influence of taste and no altering natural color of powder formulations.

Chemical method High-purity nano-silica has recently found wide-ranging applications in different fields such as pharmaceuticals, dyes, chromatography, drug delivery systems, electronic components, catalysts, and adsorbent materials. As a result, demand for high-purity silica is increasing. Combustion-derived RHA (without acid or alkali treatment) contains less than 95 wt.% of SiO₂, and the remaining part comprises different alkali oxides and impurities. With appropriate acid or alkali treatment of RH/RHA, The SiO₂ content can be increased in the system to more than 99 wt.%. Several researchers have adopted different chemical routes to derive the high-purity nano-silica.

HPLC is a dynamically developing technique widely used in almost all branches of industry and pharmaceutical, chemical, and agri-food investigations, as well as in the lab. practice and scientific research. This technique is based on the separation of target compounds from the matrix of samples containing other accompanying constituents; The chromatographic column filled with the stationary phase where the separation process takes place is named "the heart of the chromatographic system. Columns with various types of fillings are commercially available; Spherical packed columns are still the most commonly used.

Monolithic stationary phases were the subject of interest for many research groups over the last 30 years. They are often named "monolithic rods" or "silica rods" in the case of silica monolithic columns. Due to the characteristic structure that distinguishes them from traditional spherical fillings and their numerous advantages, including a low susceptibility to clogging and low flow resistance, they are a very interesting alternative for many scientists. Considering the type of material used for synthesis, monolithic columns can be divided into 2 groups; the first is based on silica gel and the second is based on polymeric materials. Vyviurska presented an exhaustive comparison of both types of commercially available monoliths [6].

The major disadvantage of most polymeric monolithic fillings is their inability to separate small molecules, hence, their significance in the analysis of samples with a complex matrix such as plant material is low.

They are mostly applied for the analysis of compounds with a high molecular weight such as proteins or polynucleotides and they have greater importance in electro-chromatographic techniques. Although polymeric monolithic columns are produced by some manufacturers such as BIA Separations (Ljubljana, Slovenia), Bio-Rad Laboratories (USA), or Thermo Scientific (Dionex Corporation) (Sunnyvale, USA), the majority of reports concern home-made fillings and, in these cases, the reproducibility of results is difficult to obtain because the process of synthesis conducted by different researchers may slightly differ.

Many published studies showed the applicability potential of silica-based monolithic columns in investigations of various samples, including plants, food, dietary supplements, and drugs. So far, numerous review papers described the analytical use of the monolithic columns. It showed applications of different types of commercially available silica-based monolithic columns in the analysis of active compounds in biological materials. It is worth noting that the Chromolith® Performance RP-18e column (100 mm × 4.6 mm) was used most commonly. The researcher presented possible applications of monolithic equipment in phytochemical analysis. Monolithic columns are also widely used in proteomics and metabolomics. ResearcherS presented detailed information on the potential applications of this kind of chromatographic filling in this research area. Our study work aims to summarize and update the possible applications of this type of fillings. The review covers papers published after 2006 and focuses on commercially available columns, as, due to the complexity and diversity of the manufacturing process, the batch-to-batch reproducibility of homemade fillings is poor. Currently, nowadays, two companies produce monolithic columns based on silica for HPLC—Merck KGaA (Darmstadt, Germany) and Phenomenex (Torrance, CA, USA). Their products are available under the trade names Chromolith® and Onyx™, respectively [7].

Rice husk is a value-added material for pharmaceuticals because rice husk produces a significant role in producing cellulose, which is used as an excipient in pharmaceuticals. Rice husk has such compatible properties, which can enhance the disintegration process with the optimum required at reach to that of standard level of pharmaceutical disintegrating agents. Rice husk-extracted celluloses are previously used as disintegrating agents in various pharmaceuticals [8].

The pharmaceutical industry has seen an increased need for carriers or excipients design that allows the controlled release of a drug in the human body. The main role of an excipient is to carry the drug for its administration under the therapeutic index. Between the new generation of excipients, the ordered Mesoporous Silica (M.S.) presents several advantages, such as excellent biocompatibility, good adsorption capacity, and precise control in drug delivery. The high cost of synthesis of mesoporous silica restricts its use in industrial applications; therefore, a low-cost procedure is necessary for widespread use. Biogenic silica from rice husk (SiO₂-rice) could be a new choice as a drug delivery system DDS. This silica is obtained from an acid leaching of rice husk followed by calcination processes at low temperatures; these conditions produce silica with good adsorption properties, similar to those of M.S. In consequence, the excipient behavior of SiO₂-rice was assessed using folic acid as the model drug, displaying an 18.5% of absorption in the SiO₂-rice pores, while MS absorbed around 19%. The drug release profiles were similar for both the silica's, suggesting that SiO₂-rice could be a low-cost, similar yield excipient for drugs similar to folic acid.

Silica Matrices—The basis for most of the products related to nucleic acid purification is the unique properties of silica matrices for selective D.N.A. binding. Types of silica materials include glass particles, such as glass powder, silica particles, and glass microfibers prepared by grinding glass fiber filter papers, and diatomaceous earth. A hydrated silica matrix, which was prepared by refluxing the silicon dioxide in sodium hydroxide or potassium hydroxide at a molar ratio of about 2:1 to 10:1 for at least about 48 hours, had been introduced in DNA. purification. DNA. binds to the inorganic matrix and is released in heated water.

The principle of silica matrices purification is based on the high affinity of the negatively charged DNA. backbone towards the positively charged silica particles. Sodium plays a role as a cation bridge that attracts the negatively charged oxygen in the phosphate backbone of nucleic acid. Sodium cations break the hydrogen bonds between the hydrogen in water and the negatively charged oxygen ions in silica under high salt conditions (pH <7).

The DNA. is tightly bound, and extensive washing removes all contaminations. The purified DNA. molecules can be eluted under low ionic strength (pH >7) later by using TE buffer or distilled water.

Besides silica matrices, nitrocellulose and polyamide membranes like nylon matrices are also known to bind with nucleic acids, but with less specificity. These materials are often used as solid-phase nucleic acid transfer and hybridization matrices. Polyamide matrices are more durable than nitrocellulose and are known to bind nucleic acids NA irreversibly. Nucleic acids can be immobilized on polyamide matrices in the low ionic strength buffer.

Glass Particle-Glass particles, powder, and beads are useful for nucleic acid purification. For example, DNA. isolation from agarose gels involved the use of chaotropic salts to facilitate the binding of DNA. to common silicate glass, flint glass, and borosilicate glass (glass fiber filter). The adsorption of nucleic acid onto the glass substrate occurs most likely based on the mechanism and principle that is similar to adsorption chromatography. Nucleic acid purification can also be done on the silica gel and glass mixture. This invention has discovered that a mixture of silica gel and glass particles can be used to separate nucleic acid from other substances in the presence of a chemotropic salt solution. Magnetic Bead-Based Nucleic Acid Purification-Magnetic separation is a simple and efficient way that is used in the purification of nucleic acid nowadays. Many magnetic carriers are now commercially available. Particles having a magnetic charge may be removed by using a permanent magnet in the application of a magnetic field. Often, magnetic carriers with immobilized affinity ligands or prepared from biopolymer showing affinity to the target nucleic acid are used for the isolation process [9].

For example, magnetic particles are produced from different synthetic polymers, biopolymers, porous glass, or magnetic particles based on inorganic magnetic materials such as surface-modified iron oxide. Materials with a large surface area are preferred to be used in the binding of nucleic acids NA.

Besides silica matrices, nitrocellulose and polyamide membranes like nylon matrices are also known to bind with nucleic acids, but with less specificity.

Besides silica matrices, nitrocellulose and polyamide membranes such as nylon matrices are also known to bind with nucleic acids, but with less specificity. These materials are often used like solid-phase nucleic acid transfer and hybridization matrices. Polyamide matrices are more durable than nitrocellulose and are known to bind nucleic acids irreversibly. Nucleic acids can be immobilized on polyamide matrices in a low ionic strength buffer.

Current Tools for Industrial Purification of mRNA.

An affinity method for RNA purification already exists. Hybridization-affinity chromatography with an oligo dT (poly-thymidine) ligand captures mRNA by its poly-A tail. About 250 mM sodium chloride suppresses electrostatic repulsion between the negatively charged backbone phosphatidic acid residues on the ligand and RNA. That enables them to approach each other closely. RNAs captured by A-T base pairing. Removing the salt reestablishes their mutual charge repulsion, overwhelms A-T hydrogen bonding, and elutes the RNA.

Hybridization-affinity with oligo dT can be used for capture, but it bears some limitations. It cannot discriminate ssRNA from dsRNA., and it cannot fractionate mRNA according to size. Intact product, incomplete transcripts, oligomers, fragments, aggregates; any species with an accessible poly-A tail elutes with all the rest. Oligo dT can be cleaned with 100 mM NaOH, but higher concentrations are not recommended. This is a concern because of the high fouling potential of IVT mixtures.

Hydrophobic-interaction chromatography (HIC) has shown valuable utility for RNA purification. With the correct choice of binding salt, DNA and ds RNA fail to bind. Incomplete transcripts elute before intact ssRNA., and NaOH is required to remove the majority of proteins. Reversed-Phase Chromatography (RPC) using styrene-divinylbenzene media also has proven useful to remove ds RNA and fractionate ss RNA by size. HIC and RPC media are prone to fouling by crude IVT mixtures. They both tolerate extended cleaning with 1 M NaOH, so they can be restored to their original condition, but fouling within a run can interfere with purification performance. This makes both of them better suited for polishing.

RNA Purification by Anion-Exchange Chromatography

Ion-exchange chromatography has served protein and plasmid D.N.A. purification for decades. Traditional exchangers such as diethylaminoethyl and quaternary amine work for RNA transcripts smaller than 500 bases, but not for large transcripts. At ambient temperature, their elevated hydrogen bonding capacity prevents them from being eluted with anything less than sodium hydroxide. Heating the buffers and columns into the range of 50°C –70°C suppresses hydrogen bonding sufficiently to enable elution with sodium chloride gradients.

Heating imposes a burden on process development and manufacturing, but it also provides a clue: An exchanger with less hydrogen bonding capacity should be able to elute RNA at ambient temperature. It verifies this prediction by illustrating the anion-exchange fractionation of mRNA from plasmid DNA at ambient temperature on a CIMmultus PrimaS column (BIA Separations).

The sample was bound at neutral pH and eluted with an ascending pH gradient. DNA. eluted before and well-separated from ssRNA Double-stranded RNA elutes slightly after DNA but still earlier than ssRNA.

Reversed-phase chromatography of ds RNA and ssRNA ladders on a CIMmultus SDVB column at 65°C; equilibration/wash buffer 0.1 M triethylamine-acetate, pH 7.0; elution buffer 0.1 M triethylaminoacetate, 25% acetonitrile, pH 7.0.

Both double-stranded species can be removed instead by a neutral pH wash step with 1 M NaCl and 10 mM E.D.T.A. Proteins are eliminated with them. Single-stranded RNA remains bound. The column is washed with another buffer to clear the excess salt, then eluted with a pH gradient. The overall purification potential of the pH gradient is increased by eliminating most of the contaminants in advance. That leaves the gradient better able to polish out its last traces. The Figure 7 reported shows the results of this approach with the DNA. plasmid and ssRNA from the previous figure. The figure reported shows results with dsRNA and ssRNA ladders. Partial size fractionation of ssRNA is evident. The wash step can be intensified by substituting guanidine-hydrochloride for sodium chloride. Combining the chaotropic salt with EDTA simultaneously relaxes nonspecific electrostatic and hydrophobic interactions, hydrogen bonding, and metal coordination. Single-stranded RNA remains bound, which creates an opportunity to scrub and remove contaminants that may have become associated with ssRNA during transcription.

Anion-exchange fractionation of plasmid DNA from ssRNA by pH gradient elution on a CIMmultus PrimaS pH column; Buffer A=20 mM Tris, 20 mM bis-tris-propane, 20 mM glycine, 50 mM NaCl, 10 mM EDTA, pH 7.0; Buffer B: 20 mM Tris, 20 mM bis-Tris-propane, 20 mM glycine, 50 mM NaCl, 10 mM EDTA, pH 11.0. Nucleic acids are from New England BioLabs.

The pH of the eluted ssRNA should be neutralized as soon as possible after elution. As in the field of protein-affinity chromatography, this is easily done by pre-aliquoting a neutralizing buffer in the fraction vessels or neutralizing ssRNA fractions immediately after the completion of the run. Brief exposure to alkaline pH produces no evidence of modification.

Like most anion exchangers, the column can be cleaned for extended periods with 1 M NaOH. Exposure to large-volume IVT mixtures generally requires treatment for about an hour. Cleaning can be enhanced by combining 1 M-3 M NaCl and 10 Mm-20 mM EDTA with the NaOH. Badly fouled columns can be restored by treatment for 16 hours-24 hours.

Elution of plasmid DNA and ssRNA from a CIMmultus PrimaS column. In one experiment, ssRNA with a size of 5,000 b was ap-

plied and eluted in a pH gradient. In the other experiment, plasmid DNA was bound and then washed off the column with 1 M NaCl, and 10 mM EDTA. Note its absence from the pH gradient except for a small doublet at about 11 minutes. Nucleic acids are from New England BioLabs.

It gives downstream developers the high-performing capture foundation needed for the purification of clinical-quality ssRNA. It provides high initial purity and removes the foulants that could interfere with polishing methods. Polishing methods that also support the removal of dsRNA, DNA, and proteins and achieve size fractionation suggest themselves as effective partners. The low salt concentration of the ssRNA coming off anion exchange enables a smooth transition to RPC. It also provides a smooth workflow with HIC. Just add salt. Both platforms should consistently deliver clinical quality ssRNA (Figure 7).

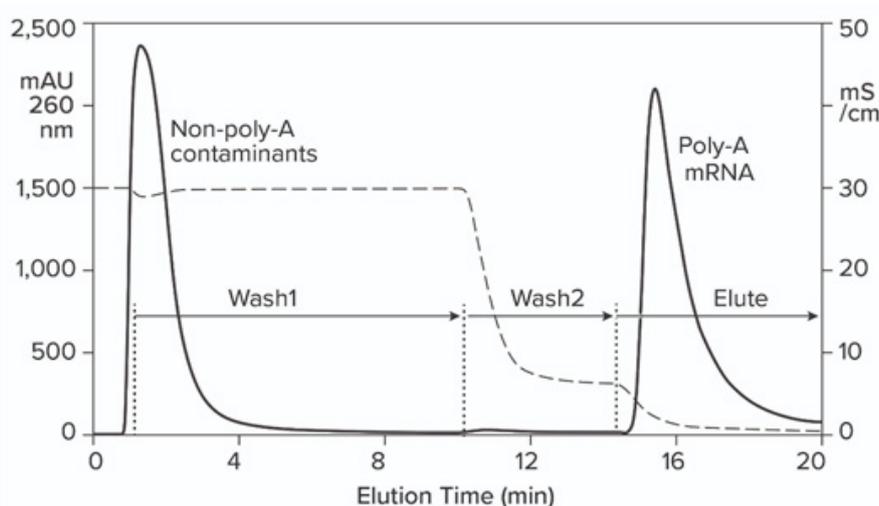

Figure 7. Hybridization-affinity chromatography of an IVT mixture on a CIMmultus Oligo dT column

Purification of Research- and Clinical-Grade ssRNA.

For purification of research-quality ssRNA, a CIMmultus PrimaS column with a salt wash before pH elution provides a one-step purification performance comparable to what protein affinity has been providing to immunologists since the 1990s. This gives researchers a simple protocol to obtain small amounts of good quality ssRNA quickly and easily to advance their studies. It gives upstream process developers an easy tool to evaluate the effects of different variables in optimizing their IVT protocols.

Contaminated columns can generate poor peak shapes, non-reproducible retention, high back pressures, and baseline artifacts. It lists the most popular stationary phases usually bonded to silica gel.

Phase subspecies—such as mixed phases (for ex, phenyl-hexyl), end-capped and non-end-capped varieties, and polar embedded phases—also exist within this bonded silica's. Various other packing materials have been used in reversed-phase chromatography RPC, including polymers, polymer-coated silica's, aluminas, inorganic-organic hybrids, coated zirconia, and graphitized carbon. Each type of phase has its advantages and disadvantages. Regeneration of Zirconia-Based HPLC Columns ZirChrom Separations, Inc. (Minnesota), has manufactured a series of zirconia-based columns. The product line has several reversed-phase columns, including polybutadiene, polystyrene, and graphitized carbon versions.

Nucleic acid purification by using ZB (Zirconia Bead) is another type of magnetic bead-based purification. These micro spherical paramagnetic beads have a large available binding surface and can be dispersed in solution. This characteristic allowed thorough nucleic acid binding, washing, and elution. The total nucleic acid isolation kit, which uses this technology for nucleic acid purification, makes use of the mechanical disruption of samples with zirconia beads ZB in a guanidinium thiocyanate-based solution that not only releases nucleic acid but also inactivate nuclease in the sample matrix. After the lysis step, the dilution of samples is done by using isopropanol. Paramagnetic beads PB are added to the samples for nucleic acid binding purposes. The mixture of beads and nucleic acid is immobilized on magnets and washed to remove protein and contaminants. Removal of residual binding solution is done with a second wash solution and finally, the nucleic acid is eluted in low-salt buffer.

At static conditions, a chromatography medium is submitted to harsh (forced) conditions, i.e. at extreme pH (HCl pH 1 or NaOH pH 14), high temperature (40°C), and long contact time (one week). Before the treatment, the chromatography medium is pre-treated. It can here be noted that the important step of the pre-treatment part is to remove any carbon-containing compounds in the storage solution of the medium (Figure 8).

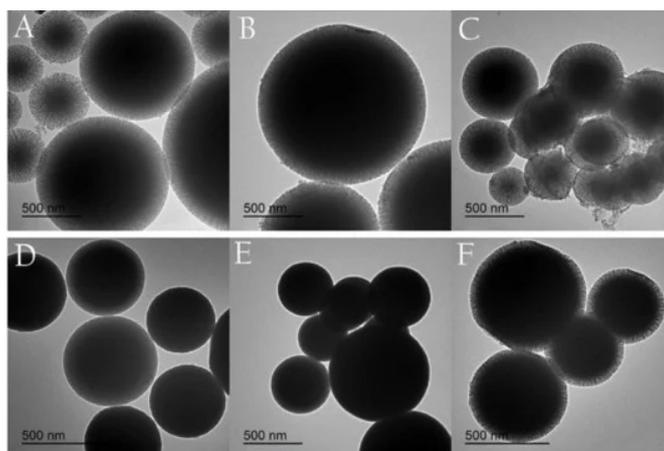

Figure 8. TEM images of G/SiO₂ composites prepared with different organic solvents as carbon sources. (A) toluene; (B) xylene; (C) mesitylene; (D) n-hexane; (E) n-heptane; (F) cyclohexane

Silica intercalated graphene-silica composites (G/SiO₂) were prepared by a 1-step hydrothermal method. In the previously reported one-step method for synthesizing G/SiO₂ composites, graphene needs to be synthesized first and then used to prepare G/SiO₂ composites. In this research work, neither the preparation of graphene nor the use of graphite as a carbon source is required for the preparation of G/SiO₂ composites. Instead, organic solvent (like toluene, xylene, mesitylene, n-hexane, n-heptane, and cyclohexane) was directly used as the carbon source, and the growth and recombination of graphene and SiO₂ were achieved simultaneously through a 1-step hydrothermal method. In a hydrothermal reaction vessel, the mixture consisting of organic solvent, TEOS, H₂O, and surfactant was uniformly stirred and then reacted at 160°C for 4 hours to prepare a G/SiO₂ composite. The influence of the type of organic solvent, hydrothermal reaction temperature, and calcination temperature on the structure of G/SiO₂ composites was studied. The morphology and structure of G/SiO₂ composites were characterized by FESEM, TEM, and Raman. The formation mechanism of the G/SiO₂ composite was proposed. G/SiO₂ composite was then grown directly on the SiO₂ spheres and used as stationary phase SP for high-performance liquid chromatography separation. A mixture of hydrocarbons was well separated under reversed phase conditions.

Highly purified amorphous silica samples (98%–99%) with a surface area in the range of 120 m²/gram to 980 m²/gram were successfully synthesized using RH from different regions of Kazakhstan. Leaching under HCl pretreatment and controlled calcination at 600°C for 4 hours revealed a decrease in the metal oxide content in the RH composition.

The purity of synthesized silica was proved by an XRF analysis. The current approach was compared with other studies that also aimed to produce silica samples from RH. The comparison was carried out to show the importance of parameters like as duration and temperature of thermal treatment, rice variety, geographical location, and concentration of used acid. The purpose of acid pre-treatment is to improve the purity and give a high surface area to the silica product during its precipitation. It proves to be an effective way for substantially removing most of the metallic and carbonaceous impurities and producing silica completely white in color.

On chemical analysis of rice husk ash, it was found that it contains about 80% Silica or most commonly known as Silica Gel. Silica Gel is considered a value-added product with commercial sale value of Rs. 200 per Kg. Silica Gel is a non-toxic, non-flammable, non-reactive material. The high surface area of the Silica Gel crystals, allows them to adsorb water easily, thus making them a useful desiccant. Once saturated with water, the gel can be regenerated by heating it to 120°C (250°F) for 2 hours. Other uses of Silica Gel include its use in Column Chromatography, insulation powder in steel mills and refrigerators, manufacturing of refractory bricks, repellents in the form of ‘vinegar-tar’, etc. With the increasing grade quality of Silica Gel, cost also increases.

The pharmaceutical industry has seen an increased need for carriers or excipients design that allows the controlled release of a drug in the human body. The main role of an excipient is to carry the drug for its administration under the therapeutic index. Among the new generation of excipients, the ordered Mesoporous Silica (MS) presents several advantages, such as excellent biocompatibility, good adsorption capacity, and precise control in drug delivery. The high cost of synthesis of mesoporous silica restricts its use in industrial applications; therefore, a low-cost procedure is necessary for widespread use. Biogenic silica from rice husk (SiO₂-rice) could be a new choice as a drug delivery system. This silica is obtained from an acid leaching of rice husk followed by calcination processes at low temperatures; these conditions produce silica with good adsorption properties, similar to those of MS. In consequence, the excipient behavior of SiO₂-the rice was assessed using folic acid as the model drug, displaying 18.5% of absorption in the SiO₂-rice pores, while MS absorbed around 19%. The drug release profiles were similar for both the silicas, suggesting that SiO₂-rice could be a low-cost, similar yield excipient for the drugs similar to the folic acid [10].

Separation is one of the most important unit operations in chemical engineering. To prepare a stationary phase with hydrophilic interaction for liquid chromatography, the use of silica microspheres as a carrier and cyclodextrin as a carbon source to prepare a carbon-coated composite by hydrothermal carbonization. Cyclodextrin and polyvinylpyrrolidone were first added to a Teflon liner containing deionized water along with the silica microspheres. After the hydrothermal reaction, the slurry-packed capillary columns containing the carbon-silica stationary phase exhibited excellent chromatographic repeatability, separation selectivity, and pH stability for polar compounds, like phenols and Endocrine Disrupting Chemicals (EDCs). Since the trade-off between the polarity and selec-

tivity, especially for polar organics, is a common issue in adsorption, Yang et al. Researcher used waste lithium-silicon powder and commercial activated carbon as resources for preparing a zeolite-activated carbon composite material, to combine the advantages of activated carbon and molecular sieve.

There are a great number of packing materials commercially available for column chromatography such as silica gel, alumina, and cellulose powder. In this study work, silica aerogel prepared using rice husk ash is used as the packing material for color separation of a purple orchid flower. The color fractions of *Cattleya bowringiana* extract had been successfully separated using silica aerogel prepared from the rice husk ash by column chromatography. The silica aerogel was prepared by sol-gel and supercritical drying at temperature and pressure of about 250°C and 5 MPa-9 MPa (850 psi) respectively. The *Cattleya bowringiana* extract was applied to the silica aerogel column (BioRad 1 cm×20 cm) for separation. Fractionation of the extract was done by elution with 50% aqueous methanol containing 0%-05% trifluoroacetic acid. 3 different colors: green, blue, and purple were successively parted from the column [11].

Silica is also used in the extraction of DNA and RNA due to its ability to bind to the nucleic acids under the presence of chaotropic. It was reported that the synthesis of value-added porous biogenic silica through rice husk ash is better than common water glass. Many researchers have investigated a study on the transformation of amorphous silica to ordered mesoporous MCM-41 or MCM-48 type silica by using pseudomorphic transformations. An advantage of this method is it produces material with a high specific surface area and highly ordered pore structure that can be used as a stationary phase in liquid chromatography LC.

In this research study, SiO₂ nanowires were prepared by using rice husks as silicon sources via a hydrothermal method. The microstructure, thermal stability, and morphology of SiO₂ nanowires were characterized by X-ray diffraction, infrared spectroscopy, thermal gravimetric analysis, and scanning electron microscope. SiO₂ nanowires with a diameter of 30 nm-100 nm were obtained and the formation mechanism of SiO₂ nanowires during the hydrothermal reaction was proposed. The SiO₂ nanowires were introduced into membrane spin columns to isolate RNA and the values of A260/280 and A260/230 were 2.0-2.1 and 1.8-2.0, respectively, which shows the SiO₂ nanowires were effective for RNA purification [12].

Even now, many silica-based products SBP are used for pharmaceutical applications such as drug delivery systems DDS, nanocomposite film for modified-release tablets, and micro particles for promising esophageal mucosal delivery systems. Therefore, proper rice hull utilization is interesting due to its ability to replace fossil resources. It is economically attractive, has wide applications in terms of energy and chemicals, and has an environmentally friendly production process. Rice hull utilization is usually executed through a calcination phase followed by extraction with an alkaline solvent to produce water glass, also known as the sol-gel method. Subsequently, the water glass is titrated with acid after which the obtained gel begins to precipitate. The precipitate is in a colloidal state, which is further aged and dried to obtain bio-silica. The developed sol-gel method has been proven to be capable of synthesizing silica with altered properties like as nano-sized and doped nanocomposites for disinfectant purposes, UV-protective material, and mesoporous thin film. Rice hull ash extraction to produce high-purity bio-silica accompanied by a full factorial design of the experiment was successfully investigated. The effects of 3 variables, like, acid concentration, RS/F, and extraction time, on the bio-silica yield and purity were investigated. Pretreatment with 1 mol/L acid resulted in around 96% of bio-silica purity. Bio-silica yield reaching 97% was also majorly affected by acid concentration, while another main factor that also had a fairly significant effect was RS/F. There was a decreased bio-silica yield of about 8-10% for extraction under RS/F 6 and 2-hours extraction time, while simultaneously increasing the acid concentration and RS/F had a synergistic effect on the bio-silica yield. This research study confirmed that high-purity bio-silica with a particle size of 5 microns to 20 microns was successfully produced from rice hull ash. The variable screening was able to cut the industrial production cost and time by half [13].

High-purity Nano-silica HPNS has recently found wide-ranging applications in different fields such as pharmaceuticals, dyes, chromatography, drug delivery systems DDS, electronic components, catalysts, and adsorbent materials. As a result, demand for high-purity silica is increasing. Combustion-derived RHA (without acid or alkali treatment) contains less than 95 wt.% of SiO₂, and the remaining part comprises different alkali oxides and impurities. With appropriate acid or alkali treatment of RH/RHA, the SiO₂ content can be increased in the system to more than 99 wt.%. Several researchers have therefore adopted different chemical routes to derive high-purity nano-silica [1].

The scientific literature review showed that most techniques include a pretreatment like acid or alkaline leaching followed by thermal treatment to increase the amount of silica produced by the reduction of carbonaceous materials. The results showed that it is possible to produce silica from RHA using simple methods and that this produced silica with purity above 98%. The treatments that afforded the best results were acid leaching followed by thermal treatment at 800°C, and alkaline extraction at low temperature, with silica purity of 99.3% and 99.6%, respectively. The results of the present study work show that it is possible to produce silica from RHA using simple processes. The various production methods tested afforded to obtain silica with purity above 98%, especially acid leaching followed by thermal treatment and sol-gel alkaline extraction at low temperatures, when silica contents were between 99.3%-99.6%, respectively. Alkaline extraction at low temperatures also produced silica particles with a large specific surface area (about 290 m²/g), compared with the other treatments evaluated, proved to be the most advantageous technique.

The purity values observed, between 98.7%-99.6%, are high, compared with data reported in the literature, especially because most studies extracted silica directly from unburnt rice husk. It was explain that one of the reasons why it is more difficult to obtain silica with purity above 97% from rice husk by direct incineration is the presence of metallic contaminants, especially potassium and sodium oxides. These compounds affect the surface of silica particles, increasing their surface area SA and reactivity, and increasing silica crystallization rate CR. Acid leaching followed by thermal treatment (LX TT 800 1 hour) induced the production of silica with the lowest carbon level (0.09%). The researcher explained that acid leaching prevents the formation of black particles since it removes potassium, the main agent responsible for the presence of unburnt carbon in ash. The authors showed that potassium works as a catalyst in the

crystallization of silica and, when the temperature rises above the dissociation temperature of K_2O (approximately $347^\circ C$), the surface of ash particles begins to melt, blocking the transportation of oxygen and CO_2 and increases the amount of the unburnt carbon. The low potassium level (0.48%) found in this sample may explain the smaller amount of carbon [14].

Amorphous silica of RHA has been widely used in vegetable oil refining, pharmaceutical products, detergents, adhesives, chromatography column packing, and different ceramic compositions [15].

Monolithic materials have been investigated as candidates for the efficient separation of chemical and biological species for many years. This research article discusses the advances in this area with particular emphasis on poly-methacrylate and silica monoliths and the use of these in the separation and enrichment of biomolecules, such as DNA, proteins, amino acids, and plasmids. A brief history of monoliths is given, followed by a more detailed discussion on the preparation methods and applications of methacrylate and silica-based monoliths that have been reported. Other monolithic materials like carbon and nanoparticle-functionalized monoliths are also described [16].

2 approaches for incorporating carbon nanotubes into monolithic columns for HPLC are described in this report. They pertain to the investigation of carbon nanotubes either as entities to modulate solute retention on monolithic columns bearing well-defined retentive ligands or as entities that constitute the stationary phase responsible for solute retention and separation. The approach involved the incorporation of carbon nanotubes into octadecyl monolithic columns while the approach concerns the preparation and evaluation of an ideal monolithic support and coating it with carbon nanotubes to yield a real "carbon nanotube stationary phase" for the H.P.L.C separation of a wide range of solutes. First of all, an octadecyl monolithic column based on the in situ polymerization of octadecyl acrylate and trimethylolpropane trimethacrylate was optimized for use in H.P.L.C. separations of small-large solutes (like, proteins). To further modulate the retention and separation of the proteins, small amounts of carbon nanotubes were incorporated into the octadecyl monolith column. In another approach, an inert, relatively polar monolith based on the in situ polymerization of glyceryl monomethacrylate and ethylene glycol dimethacrylate (EDMA) proved to be the most suitable support for the preparation of "carbon nanotube stationary phase". This carbon nanotube "coated" monolith proved useful in the HPLC separation of a wide range of small solutes including enantiomers. In this approach, more homogeneous incorporation of carbon nanotubes into diol monolithic columns (GMM/EDMA) was achieved when hydroxyl functionalized carbon nanotubes were incorporated into the GMM/EDMA monolithic support. High-power sonication for a short time enhanced further the homogeneity of the monolith incorporated with the nanotubes. In all cases, nonpolar and π interactions were responsible for solute retention on the monolith-incorporated carbon nanotubes [17].

6 new offerings have been added to the Onyx monolithic High-Performance Liquid Chromatography (HPLC) column line, including a $150\text{ mm} \times 0.05\text{ mm}$ ID choice for proteomics research. Optimized for the low flow rates commonly used for liquid chromatography/mass spectrometry LC/MS proteomics analysis, this column delivers high sensitivity for biomarker discovery. Other new column sizes include a 0.2 mm C_{18} column for higher flow rates, a $150\text{ mm} \times 0.2\text{ mm}$ trapping column, a $150\text{ mm} \times 0.1\text{ mm}$ C_8 column, and 2 ultrahigh-resolution C_{18} columns at 100 microns and 200-micron ID. The permeable Onyx media separates viscous biological samples that clog traditional columns. These columns contain solid rods of fused silica and eliminate packing issues associated with particulate media. Run times are as much as 50 % faster than with traditional columns.

Chromatography is the most prevalent technology for the large-scale purification of viral particles since it is fast, scalable, and reproducible. Purification of Recombinant Vaccinia Virus for Oncolytic and Immunotherapeutic Applications using Monolithic Column Technology [18].

Other manufacturers of monoliths are BioRad (USA) who have produced polyacrylamide UNO columns. These are advertised for their high resolution at high flow rates for protein separation. Merck has produced a silica-based monolith called Chromolith, but has concentrated on the analytical ability of the columns taking advantage of their high number of theoretical plates compared to the packed bead resins of an equivalent bed length.

Chromolith® HighResolution: High-resolution separations without ultra-high pressure. The revolutionary monolithic Chromolith® HighResolution columns are made from a single rod of high-purity monolithic silica, rather than from particles. Their unique bimodal pore structure allows the chromatographic performance to be improved significantly. Speed of analysis (separations up to 9 times faster if required) Separations 2 times faster at half the column back-pressure compared to μm columns Higher sample throughput Improved HPLC system security significantly increased column lifetime and reduced maintenance on HPLC pump and injector seals. Reduced need for sample preparation as columns are very resistant to blocking (even with biological samples). Column length no longer pressure limited. Very high separation efficiency by column coupling.

Analytical liquid chromatography of the purified labeled oligonucleotides was performed on an Agilent HPLC system, equipped with a Chromolith.

Different approaches for immobilizing affinity ligands onto stationary phases include non-covalent methods like non-specific and bio-specific adsorption, covalent coupling techniques, entrapment, and molecular imprinting. Non-specific adsorption of ligands onto support is among the earliest ligand immobilization methods reported. This technique relies purely on the physical adsorption of the ligand to support through the intermolecular forces including the Coulombic interactions, hydrogen bonding, and hydrophobic interactions. Due to its simplicity and convenience, nonspecific immobilization has been still commonly used and applied to various supports including alumina, silica, carbon or charcoal, collagen, and metals.

"Chromolith® monolithic silica columns provide an excellent solution for the separation of pharmaceutical compounds, including those pharmaceuticals analyzed by pharmacopeia methods".

This work describes a comparison of 3 types of commercial high-performance liquid chromatography silica monolithic columns with different inner diameters and generations of monolithic sorbent: a “classic” monolithic column, the first generation (Onyx™ monolithic C(18), 100 mm × 4.6 mm, Phenomenex); a “narrow” monolithic column for fast separation at lower flow rates (Chromolith® Performance RP-18e, 100 mm × 3 mm, Merck); and a recently introduced “high-resolution” monolithic column, the next generation (Chromolith® HighResolution RP-18e, 100 mm × 4.6 mm, Merck) [19].

EXPERIMENTAL PROJECT HYPOTHESIS

To verify the role played by the silica gel for chromatographic separation and purification of mRNA. It is necessary to test 3 groups of samples: purification of m RNA.

1. Using chromatographic resin silica based on synthetic origin
2. Using resin based on rice production (high purity like 99%) and with low carbon content
3. Using the same resin from rice but with not high purity like 94% and relevant carbon content

It is needed to test the purified product for carbon compound – graphene. (chemical-analytical test) the results if show significates difference ($p>0.05$) indicate a role played by the use of silica from Rice.

RESULTS AND DISCUSSION

In the last decades’ various purification methods were and are used to purify m RNA. In the research and testing field are currently used magnetic beads also covered with graphene or carbon dots. The same is used for membrane or chromatographic techniques (resin). Today are also used monoliths with composite materials. The process used for purification reported in the literature includes various phases.

TFF, the affinity of ion exchange chromatography, followed by ultrafiltration/ diafiltration. The material used is often: plastic material for TFF filtration, silica products, or another polymer.

For ultrafiltration and diafiltration various materials for the membrane are used. Of interest that a great producer of monoliths uses carbon fiber reinforcement embedded into epoxy thermoset resin (carbon fiber composite). Related to a silica column and resin it is possible to see that there is a pharmaceutical use and the synthetic one meets this quality property as required by the pharmacopeia better than the formed rice. But the same some producers provide this silica product from Rice as a pharma excipient. Some works show that the production form rice can respect the quality required by a pharmacopeia. This silica from rice varies in purity from an example of 80% -99% and shows impurity (also carbon product in example 1% more). The cost of these 2 kinds of products can explain the motivation to use or not a product.

CONCLUSION

Related to the use of graphene derivate in biopharmaceuticals it is off of interest the fact that Ribonucleic acid purification: related resin: Exemplary materials that can be used as a surface include but are not limited to acrylics, carbon (e.g., graphite, carbon-fiber). But also the role played by silica in the purification of the mRNA (resins, monoliths) or by another polymeric molecule. A great producer report into its products monoliths based on carbon composite material for purifying RNA (Carbon fiber reinforcement embedded into epoxy thermoset resin). Of great interest also to verify if the origin of this silica is used and if carbon-coated or not. If of synthetic origin or form natural product (from Rice or algae). Because due to the production process are used also real high-temperature carbon content can be funded in this resin. The silica from rice is also used in pharmaceuticals as excipients and literature report way to produce high (94%-99%) with variable concentration of impurities (1% or more). On the website of SIGMA ALDRICH is reported an interesting reference related to silica gel production for chromatography.

After seeing all reported in this work it is relevant to verify:

1. If are used in the purification of mRNA for vaccine magnetic beads or resin graphene coated or monoliths of carbon composite materials.
2. What kind of silica is used (synthetic or from rice or other natural product)?
3. The level of graphene impurity in this chromatographic stationary phase.

All this makes it possible to verify the role played by this phenomenon in the profile of impurity in biopharmaceutical production. This is relevant for regulatory, toxicological and pathological and safety need.
